[Rohrer and Arslan's nonet: More ideas regarding interactions in statistical models
statmodeling.stat.columbia.edu](http://statmodeling.stat.columbia.edu)

[I liked the causal quartet you recently posted and wanted to forward a similar homage \(in style if not
content\) Julia Rohrer and I recently made to accompany this paper. We had to go to a triple trip...](#)

Shared by [Andrew Gelman et al.](#)

Fig. 6. A triptych in homage to Anscombe. Columns show levels of the moderator variable (M). X and M are the same across rows, whereas Y has been generated according to different scenarios but maintains the same mean and variance. The slopes estimated according to a simple linear interaction model (black lines) are the same across rows, but graphing the raw data shows that the data-generating processes were quite different. Shaded regions around the regression lines show 95% credible intervals.

Shared by [Vinay Prasad MD MPH](#)

I wanted to reach out personally to share my motivation in acquiring Twitter. There has been much speculation about why I bought Twitter and what I think about advertising. Most of it has been wrong.

The reason I acquired Twitter is because it is important to the future of civilization to have a common digital town square, where a wide range of beliefs can be debated in a healthy manner, without resorting to violence. There is currently great danger that social media will splinter into far right wing and far left wing echo chambers that generate more hate and divide our society.

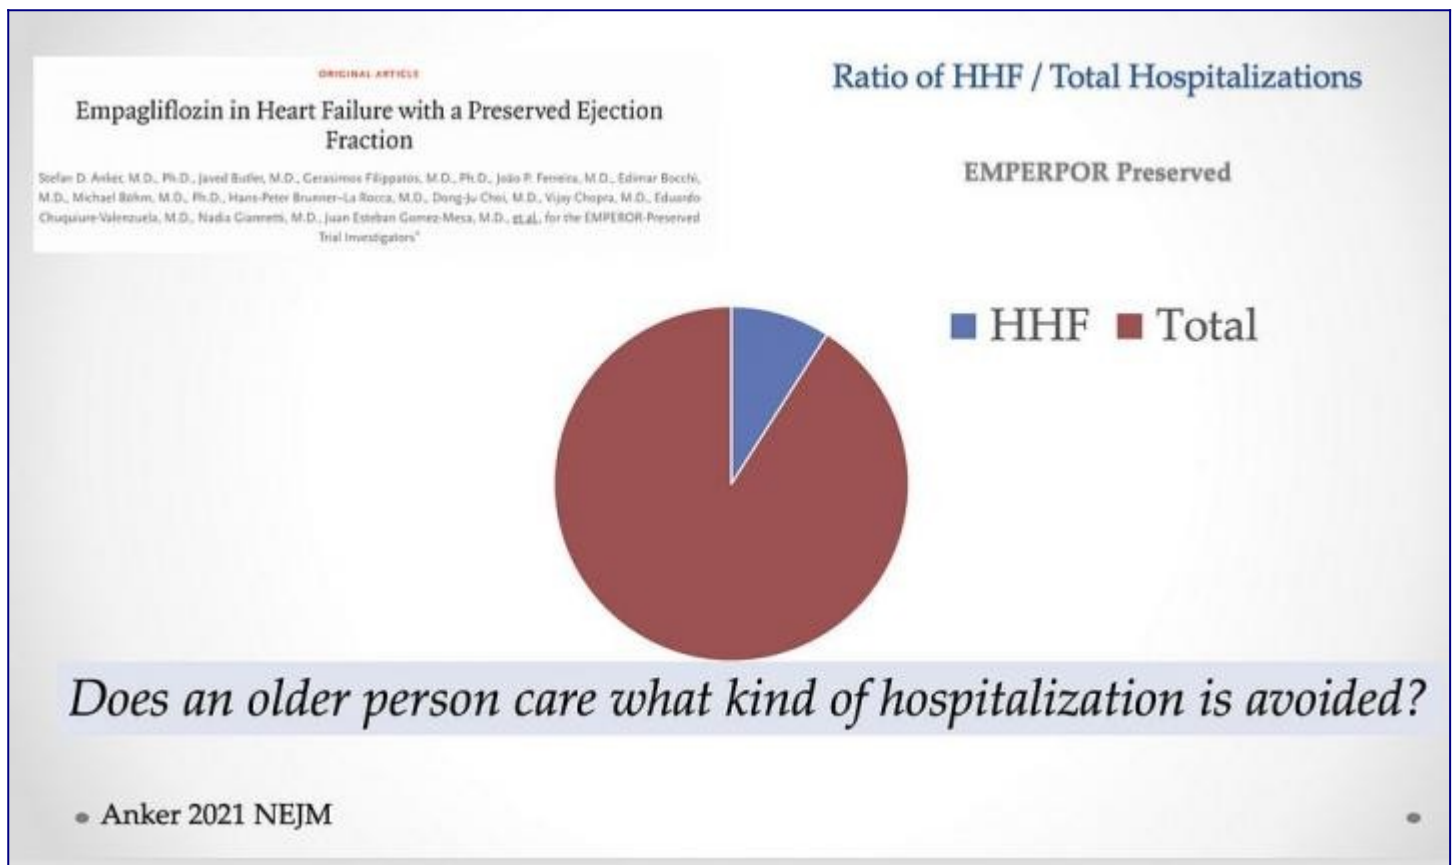

In the relentless pursuit of clicks, much of traditional media has fueled and catered to those polarized extremes, as they believe that is what brings in the money, but, in doing so, the opportunity for dialogue is lost.

NES Sparklines

For this drawing, I used an NES emulator (of my own creation) to record a snapshot of the Nintendo's RAM at each frame (60 fps) for several seconds while playing a game. The NES had just 2048 bytes of RAM! For each address in memory, I plotted its values (ranging from 0 to 255) over time as an individual sparkline. I only included addresses that changed at least once, so there are fewer than 2048 sparklines. Furthermore, I individually scaled each sparkline so as to utilize the full vertical range. Some values oscillate so rapidly that the lines can no longer be resolved when plotted - but this produces an interesting artistic effect. The sparklines are arranged in a grid-like pattern in row-major order. Because

Original Investigation

Toward a Neuroimaging Treatment Selection Biomarker for Major Depressive Disorder

Callie L. McGrath, BA; Mary E. Kelley, PhD; Paul E. Holtzheimer III, MD; Boadie W. Dunlop, MD; W. Edward Craighead, PhD; Alexandre R. Franco, PhD; R. Cameron Craddock, PhD; Helen S. Mayberg, MD

IMPORTANCE Currently, fewer than 40% of patients treated for major depressive disorder achieve remission with initial treatment. Identification of a biological marker that might improve these odds could have significant health and economic impact.

OBJECTIVE To identify a candidate neuroimaging "treatment-specific biomarker" that predicts differential outcome to either medication or psychotherapy.

Steps	Identified pitfalls	Potential solutions
Cohort building	1) Sample selection bias	Discuss design choices with an experienced clinician Use gold-standard cohort definitions Perform sensitivity analyses.
Definitions of variables	2) Imprecise variable definitions	Develop definitions in a multidisciplinary team, involving clinicians, epidemiologists, statisticians, social scientists, and patients
Feature selection	3) Limitations to deployment	Check if registration time is aligned with result time Only include information that is available at baseline Ensure there is no patient overlap between the training dataset and the test dataset
Feature selection	4) No adjustment for association between frequency of measurements and severity of disease	Consult experts and adjust variables using epidemiological or statistical strategies such as weighting, multiple imputation, or removal of unreliable variables
Study design	5) Subjective treatment allocation affecting causal inference studies	Aim to adjust for interphysician and intraphysician differences in treatment allocation
Study or results validation	6) Model overfitting and reduced generalisability to other settings	Question how local policies might affect generalisability Potentially adjust effect size estimates on the basis of known differences in prevalence

thanks for this piece. I wonder what advocates of "real world evidence" think about a lack of adherence when it's in the control group eg if they're switching to the active group. I saw a clinical trial of daily sunscreen-use where participants randomised to the 'no sunscreen' group stayed indoors or wore long-sleeve t-shirts (no effect of sunscreen was shown for nonmelanoma skin cancer)

^ | v · Reply · Share >

Frank Harrell  → Paul Brown  · 4 years ago

That's a good question that has been inadequately discussed. And yesterday's publication of a paper showing that evaluation of a workplace health program from 'real world evidence' is terribly biased when compared with a randomized trial certainly provides food for thought. I hope we get more discussion about all this.

Alex Greenfield · 5 years ago

Thank you very much for the great read! In general, your blog posts confirm many of my intuitions/beliefs, but with much more rigor, which I greatly appreciate. In the way of background, I'm a computational biologist currently working in exploratory biomarker analysis of clinical trial data.

Regarding a clinicians view of RCT not being representative - I think in many cases that's due to the biased sample of the population that is present in the RCT. For example, in oncology trials, which is where most of the RCT data I work with comes from, there is a demographic and socioeconomic bias - i.e. only relatively well off people, who live close to centers that run the trial and have the time to get there can afford to do so. Thus, the sample of the population in the RCT is different from the "real-world" population. One of my physician friends described it succinctly as: "I care much less about what happened on average between two groups in an RCT, I care about what will happen for MY two patients".

It seems that what many physicians are asking for is patient-specific predictions of response. It's clear that this is challenging largely due to confounding - we don't know which signals, molecular (i.e. mechanism of action), or clinical, are needed to fully explain response. We can have an entire separate conversation regarding what is "response" and why many current measures of response are flawed.

I would appreciate your comments on what type of data, sample size, and statistical approaches would be required in order to enable a "patient response prediction dashboard"

^ | v · Reply · Share >

Frank Harrell  → Alex Greenfield · 5 years ago

Thanks for the comments and good questions. I've dealt with some of this at <http://www.fharrell.com/pos...> . To your first point, I hark back to the intent of RCTs: not to estimate how patients in treatment A will fare but to estimate the difference in A and B. You don't need "real world" for that; that's the beauty of RCTs. As in the link just above, if you combine relative effects from RCTs with absolute risk estimates from observational cohort studies, you have what you need. In this sense, I think your physician friend is only partially

Table 1: Glossary of Terms

Term	Definition
<i>Regression to the mean</i>	When an observation is made that is distanced far from the mean value, the next observation is likely to be closer to the mean. Within individuals, a shift towards the mean can easily be confused for the effect of, for instance, a drug therapy.
<i>Causal inference methodology</i>	Research methodology that aims to structure analyses, identify, and quantify the evidence for one or more causal effects in data. Often applied in nonexperimental data.
<i>Overfitting</i>	The situation where idiosyncrasies in the data at hand are confused for generalizable associations or patterns. The risk of overfitting can be notably high when the number of model parameters is high relative to the size of the data set.
<i>Imprecision</i>	Lack of precision in the estimation, eg, reflected by wide confidence intervals for parameter(s) of interest.
<i>Power</i>	Statistical power often relates to a (binary) hypothesis test. It is the probability that the test correctly rejects the null hypothesis when a specific alternative hypothesis is true.
<i>Initial data analysis</i>	The process of data inspection after data have been collected but before formal statistical analyses.
<i>Data dredging</i>	Performing many analyses to find associations or patterns in data and subsequently ignoring the analyses in which no evidence was found when reporting the study. High risk of false positive findings.
<i>Dichotomania</i>	The tendency to dichotomize variables (eg, into "high" and "low" values) that were original measured on a continuous or a categorical scale with more than two categories.
<i>Noisy data fallacy</i>	The misconception that in data with measurement error associations are always attenuated (ie, biased towards less extreme effects).
<i>Multiple imputation</i>	A popular and flexible approach to deal with missing values in analyses, for which it is generally well known in which circumstances it leads to valid analyses and which circumstances it does not.
<i>Point-estimate-is-the-effect-ism</i>	The tendency to ignore the uncertainty of an estimated association and focus only on a single-point estimate to evaluate the strength of the association.
<i>Confounding</i>	In causal inference studies that evaluate the relation between a variable of interest (eg, a treatment) and an outcome, confounding can be caused by other variables that are a "common cause" of the variable of interest and outcome. Failure to statistically correct (eg, through multivariable regression) for important confounders can lead to residual confounding bias.
<i>Collider</i>	In causal inference studies that evaluate the relation between a variable of interest (eg, a treatment) and an outcome, a collider is a variable that is caused by the variable of interest and outcome. Unlike confounders, statistically correcting for colliders can introduce bias rather than solve it.
<i>Multivariate regression</i>	Regression with an outcome with multiple outcomes (eg, as in multivariate analysis of variance, MANOVA). Often confused with multivariable regression (multiple covariates in the regression).
<i>Table 2 fallacy</i>	The misconception that the associations between confounders and the outcome can be interpreted as valid estimates of causal associations between each confounder and the outcome.

Sample size

All sample sizes were utilized based on previous research using similar techniques in absence of power analysis (PMID: 24976214, PMID: 26568307, PMID: 11487652, PMID: 10938577, PMID: 32034128, PMID: 31661603, PMID: 30705647, PMID: 24484701, PMID: 30439419). As indicated, sample sizes are similar to those previously published using the same or similar techniques. In case of tendencies towards statistical significance, samples sizes were increased to ensure enough statistic power for analyses.

[What is the optimal way to combine multiple imputation and bootstrap to quantify uncertainty in discrimination and calibration metrics for the internal validation of diagnostic or prognostic models? ...](#)

3.2.1 Boot MI percentile

Both Schomaker and Heumann⁹ and Brand et al.¹¹ recommended calculating bootstrap percentile intervals to the estimator $\hat{\theta}_M$. This consists of

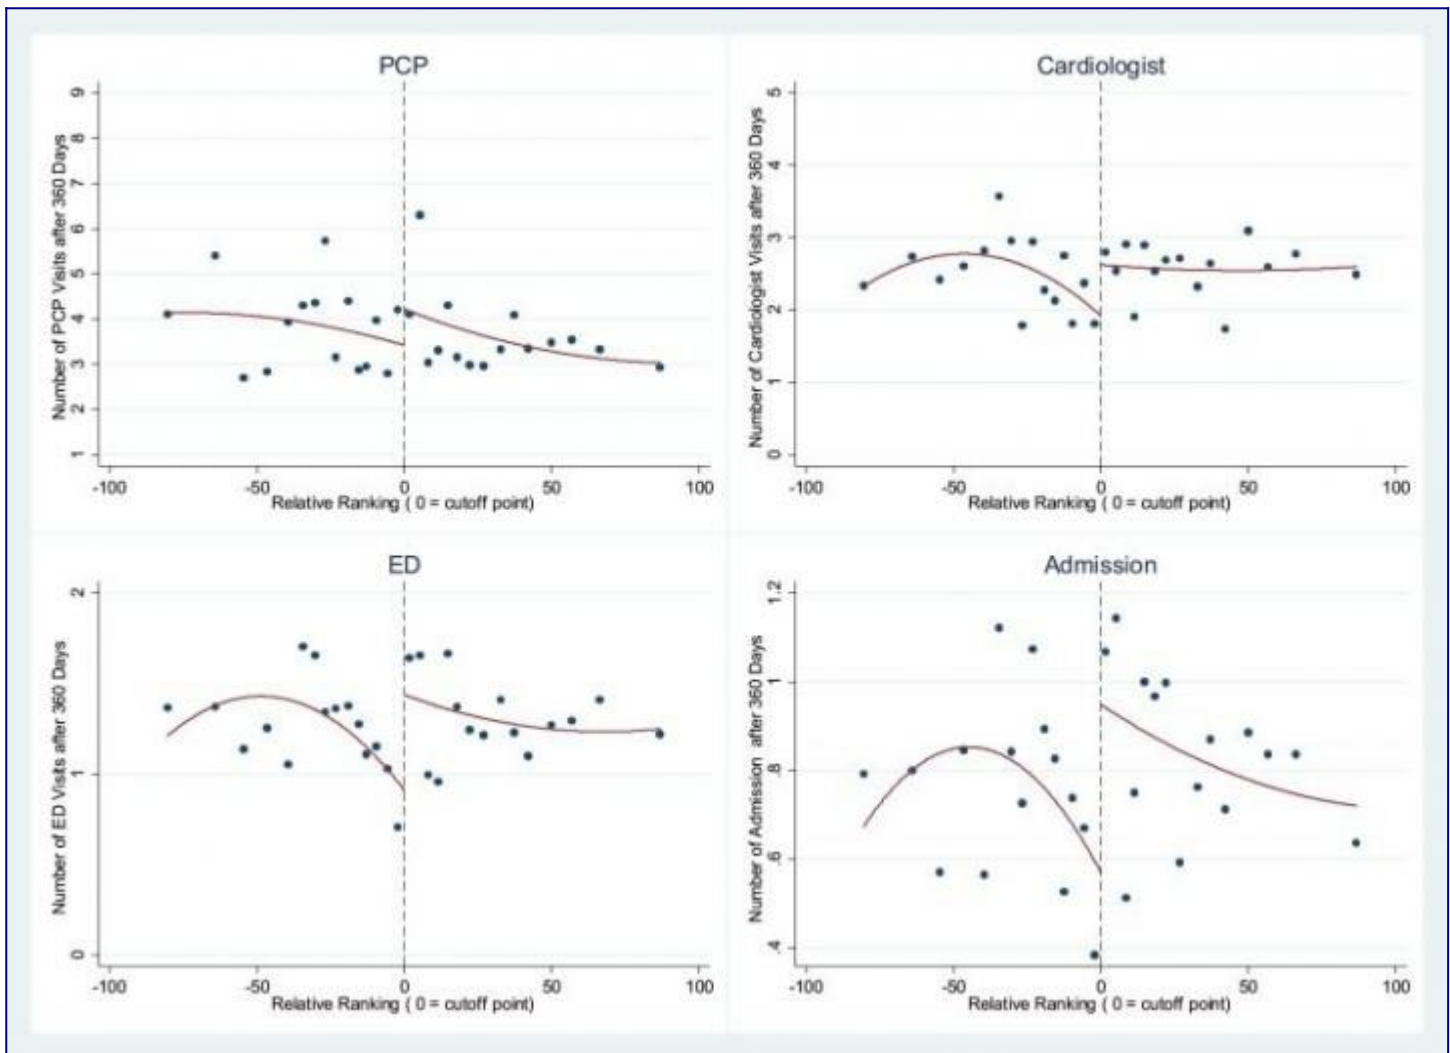

1. B bootstrap samples of the observed data are taken $Z_{\text{obs}}^{(b)}$, $b = 1, \dots, B$.
2. For each $b = 1, \dots, B$, use MI to impute missing data in $Z_{\text{obs}}^{(b)}$ M times and estimate θ in each imputed dataset, giving $\hat{\theta}_{b,m}$.
3. For point estimation of θ , one can either use $\bar{\theta}_M$ or $\bar{\theta}_{BM} = B^{-1} \sum_{b=1}^B \bar{\theta}_b$, where $\bar{\theta}_b = M^{-1} \sum_{m=1}^M \hat{\theta}_{b,m}$.
4. A $(1 - 2\alpha)\%$ percentile confidence interval for θ is then formed by taking the α and $1 - \alpha$ empirical percentiles of the $\bar{\theta}_b$, $b = 1, \dots, B$ values.

statmodeling.stat.columbia.edu

[Richard Juster points to this article, "Evaluation of Aducanumab for Alzheimer Disease: Scientific Evidence and Regulatory Review Involving Efficacy, Safety, and Futility." The article begins: On November 12, 2021, the U.S. Food and Drug Administration \(FDA\) approved the first Alzheimer's disease \(AD\) drug, Aducanumab \(Lecanemab\), for the treatment of early-stage AD. The drug is a monoclonal antibody that targets amyloid-beta, a protein that is thought to play a role in the development of AD. The approval is based on data from the EMERGE trial, which showed that Aducanumab significantly reduced amyloid-beta levels in the brains of patients with early-stage AD. However, the trial also showed that the drug had no significant effect on cognitive function or clinical outcomes. This raises questions about the value of the drug and the need for more rigorous clinical trials.](#)
